OpenMP Tasks

Remember OpenMP Sections?

Sections are independent blocks of code, able to be assigned to separate threads if they are available.

```c
#pragma omp parallel sections
{
  #pragma omp section
  {
    Task 1
  }
  #pragma omp section
  {
    Task 2
  }
}
```

There is an implied barrier at the end

OpenMP sections are static, that is, they are good if you know, when you are writing the program, how many of them you will need.

It would be nice to have something more Dynamic

Imagine a capability where you can write something to do down on a Post-It® note, accumulate the Post-It notes, then have all of the threads together execute that set of tasks.

You would also like to not have to know, ahead of time, how many of these Post-It notes you will write. That is, you want the total number to be dynamic.

Well, congratulations, you have just invented OpenMP Tasks!

OpenMP Tasks

- An OpenMP task is a single line of code or a structured block which is immediately "written down" in a list of tasks.
- The new task can be executed immediately, or it can be deferred.
- If the if clause is used and the argument evaluates to 0, then the task is executed immediately, superseding whatever else that thread is doing.
- There has to be an existing parallel thread team for this to work. Otherwise one thread ends up doing all tasks and you don’t get any contribution to parallelism.
- One of the best uses of this is to process elements of a linked list or a tree.

You can create a task barrier with:

```c
#pragma omp taskwait
```

Tasks are very much like OpenMP Sections, but Sections are static, that is, the number of sections is set when you write the code, whereas Tasks can be created anytime, and in any number, under control of your program’s logic.
OpenMP Task Example: Something (Supposedly) Simple

```c
omp_set_num_threads(2);
#pragma omp parallel default(none)
{
    #pragma omp task
    fprintf(stderr, "A\n");
    #pragma omp task
    fprintf(stderr, "B\n");
    #pragma omp task
    fprintf(stderr, "C\n");
    #pragma omp task
    fprintf(stderr, "D\n");
    #pragma omp task
    fprintf(stderr, "E\n");
}
```

Without this, thread #0 has to do everything.

- Writes `fprintf(stderr, "A\n")` on a sticky note
- Adds it to the list of tasks
- Writes `fprintf(stderr, "B\n")` on a sticky note
- Adds it to the list of tasks
- Adds the next line of code (or block of code) to the list of tasks

If You Run This a Number of Times, You Get This: (Uh-oh, what Happened?)

Run #

1  2  3  4  5

<table>
<thead>
<tr>
<th>1</th>
<th>2</th>
<th>3</th>
<th>4</th>
<th>5</th>
</tr>
</thead>
<tbody>
<tr>
<td>B</td>
<td>A</td>
<td>B</td>
<td>A</td>
<td>B</td>
</tr>
<tr>
<td>B</td>
<td>A</td>
<td>A</td>
<td>A</td>
<td>B</td>
</tr>
<tr>
<td>A</td>
<td>A</td>
<td>B</td>
<td>B</td>
<td>A</td>
</tr>
</tbody>
</table>

1. Why do we not get the same output every time?
2. Why do we get 4 things printed when we only have print statements in 2 tasks?

Not so simple, huh?

The first answer is easy. Unless you make some special arrangements, the order of execution of the different tasks is undefined.

The second answer is that we actually asked the two threads to each put two tasks on the sticky notes, for a total of four. How can we get only one thread to do this?

The “single”Pragma

```c
omp_set_num_threads(2);
#pragma omp parallel default(none)
{
    #pragma omp single default(none)
    {
        #pragma omp task
        fprintf(stderr, "A\n");
        #pragma omp taskwait
        #pragma omp task
        fprintf(stderr, "B\n");
        #pragma omp taskwait
    }
}
```

When using Tasks, you only want one thread to write the things to do down on the sticky note, but you want all of the threads to be able to execute the sticky notes.

But, if you run this, the order of printing will still be non-deterministic. If you care about order, do this:

```c
omp_set_num_threads(2);
#pragma omp parallel
{
    #pragma omp single default(none)
    {
        #pragma omp task
        fprintf(stderr, "A\n");
    }
    #pragma omp taskwait
    #pragma omp task
    fprintf(stderr, "B\n");
    #pragma omp taskwait
    #pragma omp task
    fprintf(stderr, "C\n");
    #pragma omp taskwait
    #pragma omp task
    fprintf(stderr, "D\n");
    #pragma omp taskwait
    #pragma omp task
    fprintf(stderr, "E\n");
}
```

Causes all tasks to wait until they are completed

Causes all tasks to wait until they are completed
A Better OpenMP Task Example:
Processing each Element of a Linked List

```c
#pragma omp parallel default(none)
{
    #pragma omp single default(none)
    {
        element *p = listHead;
        while( p != NULL )
        {
            #pragma omp task firstprivate(p)
            Process( p );
            p = p->next;
        }
    }
    #pragma omp taskwait
}
```

Without this, each thread does a full traversal – bad ideal!
Without this, thread #0 has to do everything!

Put this here if you want to wait for all tasks to finish being executed before proceeding.

One more thing – Task Dependencies

Remember from before: unless you make some special arrangements, the order of execution of the different tasks is undefined. Here come some special arrangements.

```c
omp_set_num_threads( 3 );
#pragma omp parallel
{
    #pragma omp single default(none)
    {
        float a, b, c;
        #pragma omp task depend( OUT: a )
        a = 10.;
        #pragma omp task depend( IN: a, OUT: b )
        b = a + 16.;
        #pragma omp task depend( IN: b )
        c = b + 12.;
    }
    #pragma omp taskwait
}
```

This maintains the proper dependencies, but, because it involves all of the tasks, it essentially serializes the parallelism out of them. Be careful not to go overboard with dependencies!

Tree Traversal Algorithms

Given a tree:

- We would like to traverse it as quickly as possible.
- We are assuming that we do not need to traverse it in order.
- We just need to visit all nodes.

```
This order could be rearranged, depending on what you are trying to do.
```
#pragma omp parallel

Traverse( root );

#pragma omp single

#pragma omp taskwait

Without this, each thread does a full traversal – bad idea!

Without this, thread #0 has to do everything – bad idea!

Put this here if you want to wait for all nodes to be traversed before proceeding

**Tree Traversal Algorithms**

**Parallelizing a Binary Tree Traversal with Tasks**

```c
void Traverse( Node *n )
{
    if( n->left != NULL )
    {
        #pragma omp task private(n) untied
        Traverse( n->left );
    }

    if( n->right != NULL )
    {
        #pragma omp task private(n) untied
        Traverse( n->right );
    }

    #pragma omp taskwait
    Process( n );
}
```

---

**Benchmarking a Binary Task-driven Tree Traversal**

```c
#define NUM 1024*1024

void Process( Node *n )
{
    for( int i = 0; i < NUM; i++ )
    {
        n->value = pow( n->value, 1.01 );
    }
}
```

---

**Parallelizing a Binary Tree Traversal with Tasks**

Traverse( A );
Parallelizing a Binary Tree Traversal with Tasks: *Tied* (g++ 10.2)

Performance vs. Number of Threads

Number of Tree Levels

Performance vs. Number of Levels

8-thread Speed-up = 6.7
F_p = 97%
Max Speed-up = 33x
Parallelizing a Tree Traversal with Tasks:
Summary

- Tasks get spread among the current "thread team"
- Tasks can execute immediately or can be deferred. They are executed at "some time".
- Tasks can be moved between threads, that is, if one thread has a backlog of tasks to do, an idle thread can come steal some workload.
- Tasks are more dynamic than sections. The task paradigm would still work if there was a variable number of children at each node.
